Introduction

Palisaded encapsulated neuroma (PEN) or solitary circumscribed neuroma is a benign neural tumor first described by Reed et al. [1] in 1972. It mainly occurs as a single, asymptomatic solitary skin-colored papule and commonly affects the nose and cheeks. Sometimes, it involves other sites, including the shoulder, upper arm, and trunk, but rarely involves the oral mucosa, including that of the lip. In our case, a 63-year-old female patient complained of a pinkish rubbery nodule on her lower lip. Histopathologic examination demonstrated a well-circumscribed nodule encapsulated by connective tissue stroma in the dermis. The nodule consisted of palisading spindle-shaped tumor cells with wavy and basophilic nuclei. The cells were arranged in streaming fascicles with multiple clefts and were strongly positive for S-100 proteins. To our knowledge, only three cases of palisading encapsulated neuroma on the lower lip have been reported in the Korean literature. Herein, we report a rare case of an oral palisaded encapsulated neuroma.

Case

A 63-year-old female patient presented with a cystic nodule on her lower lip. The lesion persisted for 6 months and gradually increased in size. The patient had no symptoms. She had a history of hypertension, for which she was taking oral medications. There was no significant family history or history of trauma to the lip. Physical examination revealed a solid and rubbery 0.4 × 0.4 cm nodule on her lower lip (Fig. 1). The nodule was completely excised, and biopsy was performed. Histological examination revealed a nodular tumor in the dermis. The tumor was well-circumscribed and partially encapsulated by fibrous connective tissue comprised of proliferating Schwann cells and axons arranged in bundles. A total of three cases of PEN on the lips have been reported in South Korean literature [3-5]. It is assumed that this is due to the characteristic of PEN, which is asymptomatic and does not occur in the oral cavity. Herein, we report a rare case of PEN on the lips, along with a review of clinical and histological features.
showed a positive reaction to S-100 proteins (Fig. 2C, 2D) and focally positive to neurofilament proteins (Fig. 2E). The above clinical and histological findings led to the diagnosis of PEN. No recurrence was observed after the complete excision.

Discussion

PEN is a benign neurogenic tumor that was first described by Reed et al. [1] in 1972. They categorized benign neurogenic tumors into three types; schwannomas, neurofibromas, and neuromas. PEN is a type of neuroma characterized by spindle-shaped cells arranged in a palisading pattern and surrounded by a connective tissue capsule [1]. Clinically, PEN appears as pinkish papules or nodules in middle-aged adults, with no sex predilection [6]. It originates from the peripheral nerves of the skin; therefore, it can
occur in all areas where these nerves are distributed. However, in most cases, it occurs on the face over the cheeks and nose. It rarely occurs on the trunk, penis, extremities, and oral cavity, including the lips \([7-9]\). PEN accounts for approximately 25\% of the nerve sheath tumors in the skin. However, it accounts for 11\% of nerve sheath tumors in the oral cavity, of which 10\% to 16\% occur on the lips \([2,10]\). PEN usually does not cause symptoms such as itching or pain and enlarges over several years.

Pathologically, it is characterized by round or oval nodules with a capsule composed of thin collagen fibers. In the nodule, spindle-shaped cells form bundles with irregular rows. Immunohistochemical examination shows that the capsule is partially positive for epithelial membrane antigen, suggesting that it is derived from peripheral nerves, and the cells in the nodule are positive for S-100 proteins \([11]\). In our case, the results of immunohistochemical staining were consistent with those of PEN. Some cases of similar lesions with unclear palisading alignment or capsule formation have been reported, and researchers have proposed calling them “solitary circumscribed neuroma” instead of PEN \([12]\). In the 2013 and 2020 World Health Organization (WHO) classification of tumors of soft tissue and bone, solitary circumscribed neuroma is described as a formal name, and PEN is described as a synonym. However, even after the WHO classification was published, these terms have been used interchangeably \([13,14]\).

The pathogenesis of PEN remains controversial. Reed et al. \([1]\) suggested that PEN is a part of multiple endocrine neoplasia syndrome type 2. However, further research confirmed that the similarity in the clinical characteristics of PEN and the neuroma in multiple endocrine neoplasia syndrome type 2 was a coincidence in the case described by Reed et al. \([1]\), and that the clinical characteristics of the two neuromas in other cases have shown many differences \([2]\). Recently, PEN has been accepted as a regenerative tumor secondary to trauma \([7,15]\). The morphological and cellular distributions of PEN and traumatic neuroma are found to be similar. Leblebici et al. \([9]\) reported that PEN shows an increase in small-diameter peripheral nerve fibers similar to that in traumatic neuroma around the lesion. The lip is frequently damaged by teeth or food unconsciously; hence, we thought that this minor trauma might have led to the occurrence of PEN in our case.

Clinicopathologically, PEN in the oral cavity can be differentiated from neurofibroma, traumatic neuroma, and Schwann cell tumors. Unlike PEN, a neurofibroma does not have a capsule, the tumor cells are scattered, and a palisading pattern is not observed \([13]\). A traumatic neuroma appears after a history of trauma and is commonly accompanied by pain, burning sensation, or paresthesia. Additionally, infiltration of inflammatory cells around or inside the tumor cells can help differentiate a traumatic neuroma from PEN \([16,17]\). Although a Schwann cell tumor is surrounded by a capsule similar to that in PEN, it does not contain axons in the intracapsular part; therefore, it shows negative immunohistochemical staining for neural filaments, and the Antoni type A and B tissue is an important differentiation point.

PEN is usually treated by simple excision and rarely grows again, even after partial excision. Initially, our provisional diagnosis was a mucocele, which is a common asymptomatic lesion of the lip having a color similar to that of the mucosa. Although oral neural neoplasms are uncommon, they should be included in the differential diagnosis, and an accurate diagnosis should be made after an immunohistochemical examination.

Notes

Ethical statements

This study was approved by the Institutional Review Board (IRB) of Inje University Busan Paik Hospital (IRB No: BPH 2021-01-001). Written informed consent was obtained from the patient for the publication of this case report and accompanying images.
